MASSA:
Mobile Agents Security through Static/Dynamic Analysis

ABSTRACT
Existing MASs suffer from security problems that must be solved, if mobile code is to be used in the development of mission-critical, real-world applications. In this paper we propose a framework that provides automated support for verification and analysis of MASs and allows for identifying security issues before the MASs are placed into action. The proposed approach is centered around an abstract reference model and combines static and dynamic security analysis techniques explicitly tailored to mobile agent systems. Our preliminary work shows that, in the cases we studied, appropriate analysis techniques facilitate the identification of security vulnerabilities in MASs.

Keywords
Mobile Agent Systems, Security Analysis, Static Analysis

1 INTRODUCTION

Mobile code technologies [5, 8] are attracting a great deal of interest from both industry and academia. In particular, the mobile agent paradigm has been used successfully to design applications ranging from distributed information retrieval [9], to network management [2], to wireless-based services for dynamically reconfigured network links [15].

Although the mobile agent paradigm provides a number of advantages with respect to the traditional client-server paradigm, some fundamental issues must be addressed for this new approach to be universally accepted. In particular, security and verification issues cause major concerns among potential users of mobile agent systems. *Mobile Agent Systems* (MASs) provide a distributed computing infrastructure composed of *places* where agent-based applications belonging to different (usually untrusted) users can execute concurrently. The places that compose the infrastructure may be managed by different authorities (e.g., a university or a company) with different and possibly conflicting goals, policies, and security requirements, and may communicate across untrusted communication infrastructures, such as the Internet.

Although the security issues related to the use of MASs have been studied in different contexts by both the distributed systems and the computer security communities, the results achieved in these fields have seldom been used either to secure existing MASs or to design and implement secure new MASs. Unfortunately, MASs are often proof-of-concept prototypes whose focus is on mobility mechanisms, and security is left as future work. Some existing systems do provide some basic mechanisms for security and for the definition of security policies, but these mechanisms are usually primitive. Moreover, the security mechanisms available today are far from providing a sound, comprehensive security solution—the results achieved to date address only a subset of problems and provide only specific solutions for such problems (e.g., [11, 16]).

In short, existing MASs suffer from security problems. These limitations must be overcome if mobile code is to be used in the development of mission-critical, real-world applications. To solve these issues, we need a general solution that, independent of the particular mobile agent technology under consideration, is able to guide and support developers in the analysis of security issues during the design and implementation of services and applications.

In this paper, we propose a framework that provides automated support for modeling and analysis of security issues in the development of secure mobile agent systems. By doing so, the framework allows for an early verification of MASs, before they are placed into action. The framework is based on a novel approach that integrates static and dynamic analyses so that the results from the former can be used to guide the latter and vice versa. This integration is achieved through the presence of an overall abstract reference model.

Our preliminary results show that, in the cases we studied, appropriate analysis techniques facilitate identification of security vulnerabilities in MASs. In particular, we have successfully applied dynamic, black-box techniques to identify threats for the security of MASs, and static, white-box techniques to early diagnosis of the possible presence of such threats. We are convinced that further research can identify the types of analyses needed to evaluate the security of existing mobile agent systems and thus provide guidance in developing new secure mobile agent systems. In particular, we believe that the complementary use of static and dynamic analysis techniques is the key to addressing many security problems in a general and efficient way.

2 A FRAMEWORK FOR EVALUATING THE SECURITY OF MOBILE AGENT SYSTEMS

We aim at addressing the problem of analysis and verification of the security of mobile agents systems. Our overall goal is to define a general approach for the verification of MASs that is able to provide both the developer and the user of a MAS with a higher level of confidence in the security mechanisms provided by the system. We are convinced that such assurance is the necessary prerequisite for the widespread acceptance of applications based on mobile agents. To this end, we propose a framework that is composed of a reference model and a set of static and dynamic analysis techniques. The reference model lets us develop a general approach to the problem of MAS security by abstracting security mechanisms and by defining attack classes in a technology-independent way. The set of dynamic techniques consists of a library of attack patterns defined on the reference model. The attack patterns focus on the authentication, authorization, and accounting functionalities provided by MASs. The attack patterns can be instantiated into actual agents that perform particular tests on the system under analysis. The set of static techniques consists of program analysis techniques that are existing techniques that we adapt or extend, novel approaches that we develop, or combinations of techniques that we integrate. We will use the techniques to perform analysis of the code that implements the security mechanisms in MASs (e.g., analysis of exceptions and escape analysis for the proposed example, as shown in Section **??**).

We use the framework to verify whether a given MAS is secure using the following approach: (1) map the MAS onto the reference model; (2) based on the mapping between the model and the MAS, identify a set of security issues for the system; (3) analyze the involved security mechanisms of the MAS using static and dynamic analysis techniques; and (4) if necessary, extend the framework to account for new characteristics of MASs or new classes of threats to their security. Beside its generality, one major advantage of the framework is that it allows for automation. Some of the steps, such as 2 and 3, can be fully automated, whereas the rest can be at least partly supported by suitably defined tools.

A REFERENCE MODEL FOR SECURITY ANALYSIS

As discussed in the Introduction, existing approaches for assessing the security of mobile agent systems lack generality and in many cases address only specific problems. To provide a general approach to the problem of MAS security, we first define a reference model that can help in abstracting security mechanisms and in defining attack classes in a way that is independent of a specific technology. In this way, we can factor the knowledge gathered through the analysis of different systems, and leverage previous experience in evaluating the security of MASs. The definition of an abstract reference model has several advantages: (1) it provides common concepts, abstractions, and terminology for the security analysis; (2) it allows for highlighting the security *abstractions* available in the different languages; and (3) it supports the definition of general attack classes that can then be instantiated on particular systems.

We propose a reference model, defined based on the analysis of a number of existing systems and their security models [10, 12, 14, 18]. The model is described in details elsewhere [7].

SECURITY ANALYSIS TECHNIQUES FOR MASs **??**

We use the reference model described in the previous section as a basis for identifying a set of security threats (i.e., possible attacks patterns) and analysis techniques to address them. For example, in the case of authorization mechanisms, the security threats can be identified by means of an *access matrix*. Intuitively, the access matrix helps to identify the possible *access space* for a component: that is, what other components in the model can be accessed (e.g., by means of an object reference or a file descriptor). The analysis of a system is performed by analyzing the different access matrices and filling in the types of access allowed between components implemented in the particular system. For each possible access, the possible operations and subset of these operations that would actually be permitted must be determined. Then each operation is exercised and the outcome is verified against the defined policy.

Once the possible threats to security are identified on the model, the attacks are mapped onto the particular MAS under analysis. This provides an instantiation of the attack pattern for dynamic analysis and defines the element of the MAS implementation to be verified using static analysis techniques. As an example, consider an attack pattern aimed at the disclosure of a MAS code repository and an attack pattern whose goal was to exercise the access to the MAS policy database. The code disclosure attack pattern can be informally expressed as follows: (1) raising of uncaught exceptions; (2) inspection of the stack to collect class names; (3) use of reflection classes to gather information on the code repository through the class names previously identified; and (4) identification of static methods in the code repository. The policy database attack pattern is "triggered" by the fact that a reference to the class implementing the policy was obtained from the execution of the previous attack. The policy database attack pattern can be expressed as follows: (1) obtain a reference to the policy component; (2) exercise read access on all the elements of the component API; and (3) exercise write access on all the elements of the component API. These two attack patterns were instantiated in the context of the Aglet system [1] and led to a compromise. The attacks let us spot the specific chain of problems causing the vulnerability: (1) the "tricky" interaction between the agent and the MAS was not anticipated by the designers of the Aglet security system (i.e., an aglet is not supposed to access the policy database); (2) as a consequence, modifications to the policy database are not thoroughly checked by the Security Manager.

The analysis of this vulnerability provides input and scope for the corresponding, complementary static analysis. For this vulnerability, we have identified two static analysis techniques that are suitable: exception analysis and escape analysis. In previous work, we developed techniques to represent exception-handling constructs [17] that enable the detection of exceptions that can be raised within a system and are not caught by any exception handler. In previous work, we also adapted existing escape analysis techniques [3, 4, 6, 19], which can identify a set of methods that are accessible through the interface of a MAS but are not part of the published API of the system [13]. The ability to identify all exceptions that are raised, but not handled, within the Aglet system will let us provide a warning about possible security problems to the MAS developer. With escape analysis, we can identify the set of methods that are accessible through the interface of the Aglet system but not part of the published API of the system.

This example illustrates the general approach that we propose. The approach, as we stated above, is to use dynamic techniques to identify security vulnerabilities, and then develop static analysis techniques that are appropriate for the identification of the problem(s) causing such vulnerabilities. By doing this, we can populate the framework with a rich set of analysis techniques that address different security issues.

The techniques we develop will depend on the security vulnerabilities we find during our dynamic analyses. We will build on our previous work in analysis, and adapt, extend, develop, or combine techniques required for detecting security threats. The main problem with this use of static analysis techniques is that, due to their computational cost in terms of both space and time, practical techniques usually compute conservative approximations of the results. This approximation can lead to the reporting of spurious results when evaluating the security of a MAS. For example, the analysis the Aglet system may identify several public static methods, even if the method used to access the Aglet policy database is the only method actually "dangerous" for the system.

We account for this problem in two ways. First, we adapt and/or extend the static analysis techniques. More precisely, we can adapt an analysis by tuning its precision (to decrease the number of spurious results) or can extend the analysis technique by including different kinds of analyses (to "filter" the results and thus increase the accuracy of the results). For example, the addition of an analysis of the Security Manager to verify which accesses to the system are checked and which ones are not may rule out some of the methods identified by escape analysis. Second, we use static and dynamic analysis jointly, when the results of the former are too imprecise to be useful. In this second case, the results of the static analyses will be still useful to avoid performing part of the dynamic analyses, so as to increase the efficiency of the overall analysis. In general, the static analysis techniques that we consider are safe, and therefore their results can be used to guide the dynamic analysis by pruning the analysis space.
