ABSTRACT

Non-Fungible Tokens (NFTs) have emerged as a way to collect digital art as well as an investment vehicle. Despite having been popularized only recently, NFT markets have witnessed several high-profile (and high-value) asset sales and a tremendous growth in trading volumes over the last year. Unfortunately, these marketplaces have not yet received much security scrutiny. Instead, most academic research has focused on attacks against decentralized finance (DeFi) protocols and automated techniques to detect smart contract vulnerabilities. To the best of our knowledge, we are the first to study the market dynamics and security issues of the multi-billion dollar NFT ecosystem.

In this paper, we first present a systematic overview of how the NFT ecosystem works, and we identify three major actors: marketplaces, external entities, and users. We then perform an in-depth analysis of the top 8 marketplaces (ranked by transaction volume) to discover potential issues, many of which can lead to substantial financial losses. We also collected a large amount of asset and event data pertaining to the NFTs being traded in the examined marketplaces. We automatically analyze this data to understand how the entities external to the blockchain are able to interfere with NFT markets, leading to serious consequences, and quantify the malicious trading behaviors carried out by users under the cloak of anonymity.

1 INTRODUCTION

A Non-Fungible Token (NFT) is an ownership record stored on a blockchain (such as the Ethereum blockchain). While digital items, such as pictures and videos, are the most common assets traded as NFTs, the sale of physical assets, e.g., postal stamps [34, 46], gold [48], real estate [38], physical artwork [20], etc., is also steadily gaining popularity. In the cryptocurrency world, an NFT is the equivalent of a conventional proof-of-purchase, such as a paper invoice or an electronic receipt. Among other things, what make NFTs attractive are verifiability and trustless transfer [72]. Verifiability means that sales are recorded as blockchain transactions, which makes tracking of ownership possible. In addition, the NFT concept allows for the trading of digital assets between two mutually distrusting parties, as both the crypto payment and the asset transfer happen atomically in a single transaction.

Several NFT marketplaces (NFTMs), e.g., OpenSea, Rarible, and Axie, emerged in recent years to facilitate buying and selling NFTs. This has sparked the interest of both crypto art collectors and traders. To put things into perspective, OpenSea, the largest NFTM, collected $236M USD in platform fees generated out of a trading volume of $3.5B USD [15] in August 2021 alone. This is around half of the volume [25] generated by the e-commerce giant eBay during the same period. And the all-time combined trading volume of the top three NFTMs—OpenSea, Axie, and CryptoPunks—surpassed $10B USD in September 2021 [11]. Individual NFT sales have also skyrocketed in recent months [64], with nine out of ten of the most expensive sales [1] taking place between February and August 2021. For example, the media widely reported on the digital artist Beeple, who sold an art piece for $69.3M USD; as another example, the first tweet of Twitter CEO Jack Dorsey was sold for $2.9M USD. Also, NFTMs have surfaced as the most gas-eating Ethereum contracts. For example, OpenSea made it to the top of the list of gas-guzzlers in EtherScan [50], consuming around 20% of the gas spent by the network.

As the NFT space exploded with multi-million dollar sales, cybercriminals and scammers have inevitably flocked to the markets to make quick profits and cheat unsuspecting users. As a result, numerous NFT scams also made recent headlines.

Legitimacy is one of the big issues with NFTs, as nothing prevents an impostor from “tokenizing” and selling someone else’s art, while the creator remains oblivious of the fraud. With the current state of affairs, the onus of verifying the token is on the buyer. Unfortunately, this is not always easy. For instance, in August 2021, a perpetrator impersonated the popular British graffiti artist Banksy and sold an
NFT [19] that featured a “fake” art piece by the artist for $336K USD through an online auction. While NFTMs try to thwart such attacks by mandating account validation, typically through an artist’s social media presence, another scammer punched a hole through RARIBLE’s verification process and managed to get a fake account associated with the renowned artist Derek Laufman verified [32]. Counterfeits NFTs, also called copycats or parody projects, resemble reputable collections and purport to have been created by reputable sources. For example, the early NFT project CryptoPunks has numerous clones, such as CryptoPhunks. In some scenarios, scammers set up unauthorized customer support channels and social media accounts that pretend to be affiliated with NFTMs in an effort to steal customer information and compromise accounts [40]. Also, there is evidence of rug-pulls, where the owner/creator of an NFT unscrupulously hypes an asset in order to inflate its value, only to cash out, leaving others to suffer from the subsequent decline in value. One such example is the Eternal Beings collection, which was promoted by the popular American rapper Lil Uzi Vert through his Twitter account with 8.5M followers. Soon after the initial investment by the buyers, he deleted all of his tweets, causing the token values to plummet [41].

With enormous funds flowing into decentralized finance (DeFi) applications, scams have become lucrative money-making opportunities. Previous research studied several different aspects of crypto-economic attacks, e.g., financial repercussions due to transaction reordering [52, 54, 66, 76], flash loan abuse [67], arbitrage opportunities [75], and pump-and-dump schemes [56, 61, 73]. Besides protocol attacks, there also exists a substantial body of work on automated detection of smart contract vulnerabilities, e.g., reentrancy, transaction order dependence, integer overflows, and unhandled exceptions [16, 30, 49, 51, 55, 57–60, 63, 65, 69, 74]. To the best of our knowledge, however, the existing literature has not explored the security challenges in the emerging NFT ecosystem, or performed a systematic and comprehensive analysis of the associated threats. Our work fills that void. First, we identify three components constituting the NFT ecosystem. We then analyze each component to discover security, privacy, and usability issues, as well as economic threats. We hope that our work will be helpful both for NFT marketplaces and their users. We envision this paper as a guide to help NFTMs to avoid mistakes while making users aware of the perils of the NFT space. In particular, we make the following contributions:

**Anatomy of the NFT ecosystem.** We systematize the NFT ecosystem, looking at the participating actors—marketplaces, external entities, and users—and we analyze their mutual interactions (Section 3).

**Comprehensive data collection.** We leverage multiple sources of data, including the Ethereum blockchain, as well as asset and event data sourced from the NFT dApps, to paint a holistic picture of how the ecosystem operates (Section 4).

**Identifying irregularities in NFTMs.** We identify flaws in the NFTM designs, which, if abused, pose a significant financial risk.

**Identifying issues with external entities.** We identify the off-chain external entities connected to the NFT ecosystem, and how such entities can pose threats to users (Section 6).

**Uncovering malicious user behaviors.** We discover and quantify trading malpractices, such as wash trading, shill bidding, and bid shielding, which are taking place in the top marketplaces. The insight drawn from our analysis sheds light on some of the prime factors responsible for driving up the recent NFT frenzy (Section 7).

**Releasing code and data.** We open-source our analysis framework along with the data we collected to help researchers uncover further interesting insights about the emerging NFT economy.

## 2 BACKGROUND

In this section, we introduce the building blocks of the Ethereum ecosystem, with an emphasis on non-fungible tokens (NFTs) and the economy that has grown around them.

### The Ethereum Blockchain

Ethereum is the technology powering the cryptocurrency Ether (ETH) and thousands of decentralized applications (dApps). The Ethereum blockchain is a distributed, public ledger where transactions are mined into blocks by miners who solve cryptographic Proof of Work (PoW) challenges. In this ecosystem, an account is an entity represented by an address that is capable of submitting transactions. There are two types of accounts in Ethereum: externally owned accounts (EOA), which are controlled by anyone holding the corresponding private key, and contract accounts, which contain executable pieces of code, called smart contracts. A smart contract is a program run by the Ethereum Virtual Machine (EVM), which leverages the blockchain to store its persistent state. A transaction is the transfer of funds between accounts, or an invocation of a contract’s public method. The address that sends the funds or interacts with the contract is denoted by msg.sender.

### Non-Fungible Token (NFT)

In the real world, tokens are representations of facts, such as the position in a queue or the authorization to access a facility. In Ethereum, tokens are digital assets built on top of the blockchain. Unlike Ether, which is the native (built-in) cryptocurrency of the Ethereum blockchain, tokens are implemented by specialized smart contracts. There are two main types of tokens: fungible and non-fungible. All the copies of a fungible token, usually conforming to the ERC-20 interface [71], are identical and interchangeable. Such tokens can act as a secondary currency within the ecosystem, or can represent someone’s stake in an investment. On the other hand, all the copies of non-fungible tokens, usually conforming to the ERC-721 [53] interface, are unique, and each token represents someone’s ownership of a specific digital asset, such as ENS domains [18] and CryptoKitties [7], or a physical asset, like a gold bar.

ERC-721 [53] is by far the most popular standard for implementing non-fungible tokens on Ethereum. The standard interface defines a set of mandatory and optional API methods that a token contract needs to implement. Figure 1 presents a few of those API methods relevant to our discussion.

```solidity
setApprovalForAll(address _operator, bool _approved) external
approve (address _operator, uint256 _tokenId) external payable
transferFrom (address _from, address _to, uint256 tokenId) external payable
tokenURI (uint256 _tokenId) external view returns (string)
```

**Figure 1:** Important methods defined in ERC-721.

Each NFT has its own ID (to keep track of these unique tokens), which is referred to as _tokenId. In ERC-721, an operator is an entity that can manage all of an NFT owner’s assets. In other words, an NFT owner can delegate the authority to act on her assets to
Figure 2: Anatomy of the NFT ecosystem showing all the marketplace actors, and their mutual interaction. The dotted and solid lines indicate data-centric and command-centric communication channels, respectively.

3 ANATOMY OF THE NFT ECOSYSTEM

In this section, we provide an overview (Figure 2) of the economy that has developed around NFTs. Specifically, we identify the actors that participate in the ecosystem and the components they interact with.

Users. NFTs are often used to sell digital collectibles and artwork, e.g., images, audio files, and videos. The users in the NFT ecosystem belong to one of three categories: content creator, seller, and buyer. First, the creators create digital content and upload it to hosting services (an external entity) to make the art publicly available. When it comes to selling the content, some creators are not technical enough to turn their art into an NFT, and put it as a token on the blockchain. Therefore, they authorize sellers to mint NFTs and offer it on marketplaces. In other cases, a content creator is also taking the role of the seller. Once listed on a marketplace, buyers can buy the artwork at a listed price, make offers, or place bids. If their offer is accepted or they win an auction, the NFT is transferred by invoking the transferFrom() API (Section 2) from the seller to the buyer to reflect the change in ownership.

Marketplaces. NFT marketplaces (NFTM) are dApp platforms where NFTs (also referred to as assets) are traded. There are typically two main components of an NFTM—a user-facing web frontend, and a collection of smart contracts that interact with the blockchain. Users interact with the web app, which, in turn, sends transactions to the smart contracts on their behalf. Primarily, there are two types of contracts: (i) marketplace contracts, which implement the part of the NFTM protocol that interacts with the blockchain, and (ii) token contracts, which manage NFTs. Marketplaces typically allow users to perform the following activities: (a) user authentication, (b) token minting, (c) token listing, and (d) token trading. The token-related activities are collectively called events. Depending on where these events are stored, three broad types of NFTM protocol design are possible: (i) on-chain: all the events live on the blockchain. Since every action costs gas, this design makes the NFTM operationally expensive for the users. NFTMs that follow this design include AXIE, CRYPTOPIKES, FOUNDATION, and SUPERRARE. (ii) off-chain: the events are recorded in a centralized, off-chain database managed by the NFTM. Users perform various activities by interacting with the web app, not the blockchain, and, therefore, this design is gas-friendly. Nifty is an example of an off-chain NFTM. (iii) hybrid: depending on their type, events are stored either on-chain or off-chain. To ensure the integrity of the operation, on-chain and off-chain events are tied together with a cryptographic check. OPENSEA and RARIBLE follow this model.

User authentication. Users first need to register with the NFTMs to access their services. Post-registration, two different authentication workflows are possible: (a) classic credentials-based (username/password), or (b) signature-based. With the latter, the user is first asked to sign a challenge string. Then, the marketplace recovers the address of the signer (user) from the elliptic-curve signature. OPENSEA, RARIBLE, FOUNDATION, CRYPTOPIKES, and SUPERRARE follow this model. Since Ethereum private keys are essentially unguessable [28], this authentication method is generally more secure than traditional passwords (passwords are typically drawn from a limited set of characters, shorter in length, and easier to brute-force).

Token minting. A token is minted (created) by calling the appropriate method of the token contract, which generally complies with the ERC-721 or ERC-1155 standard. A single token contract can...
manage the ownership of a number of NFTs. Every NFT is assigned an integer called _tokenId. Therefore, an NFT is uniquely identified by the (token_contract_address, _tokenId) pair on the blockchain. A “family” of NFTs, which are either similar, or based on a common theme, called a collection, e.g., CryptoPunks. An NFT can be minted in many different ways: (a) default contract: the token is minted as part of a pre-deployed, designated token contract managed by the marketplace. NFTMs like OpenSea, Foundation, SuperRARE, etc., provide a default contract to hold NFTs when no custom contract is deployed by the creator. (b) replica contract: the NFTM itself deploys a contract on behalf of the creator to manage the collection that the NFT is a part of. Deployed contracts have identical bytecode, but are customized through initialization parameters. Examples of such NFTMs includes Nifty and Rabille. Since both default and replica contracts are managed by the NFTM, together they are called internal token contracts. (c) external contract: the creator independently deploys a custom contract to manage the collection, and later imports it to the marketplace. To be interoperable with the NFTMs, external contracts must follow a well-established token standard. Otherwise, a custom integration is needed. OpenSea and Rabille allow external contracts on their platforms. A single token contract can manage one or more collection. Typically, replica or external contracts manage a single collection, while the marketplace default contract manages several. In the latter case, the NFTM dApp maintains an off-chain association between the set of _tokenId ands the collection those belong to.

- **Token listing.** Once created, a seller lists their assets for sale. To list an NFT on a platform, some NFTMs, e.g., Foundation, SuperRARE, Nifty, mandate either the seller or the entire collection (that the NFT is a part of) to be verified. Even for the NFTMs where verification is optional, for example, OpenSea, Rabille, getting an artist or a collection verified provides credibility and increases buyers’ confidence. NFTMs display special badges on verified profiles of artists and collections, which helps in building a brand, and receive preferential treatment to boost sales – such as search priority and safe-listing to suppress safety-related alerts before the purchase.

- **Token trading.** Buyers can make offers, or place bids on the assets on sale. When an offer is accepted, or an auction is settled, the NFTM transfers assets from the seller’s account to the buyer’s. Usually, this is when the NFTMs charge a fee for the service they offer. A few key aspects of the NFTM bidding system are discussed below: (i) Pricing protocol: The bid price can either increase or decrease with every bid. An English auction, the bid opens at a reserve price, which is the minimum price the seller is willing to accept for an NFT. Subsequent bids from the buyer gradually increase the price. The NFT goes to the highest bidder. The English auction approach is used by most NFTMs, e.g., OpenSea, Foundation, and SuperRARE. In a Dutch auction, the bid opens at a high price. Subsequent bids from the seller gradually decrease the price. The NFT goes to the bidder who first accepts a bid. Axi follows the Dutch auction pattern. (ii) Bid storage: Bids can be stored either on-chain, e.g., CryptoPunks, Foundation, SuperRARE, or off-chain, e.g., Nifty, Rabille, OpenSea. There are protocols, such as Wyvern used by OpenSea, which keep both the sell order (listing) and the bids off-chain for gas efficiency, though the order matching and the NFT transfer happen on-chain. Therefore, the marketplace contract cryptographically verifies the buy order against the associated sell order to prevent a malicious buyer from either buying an item that is not on sale, or tampering with an existing sell order. (iii) Active bids: Some NFTMs disallow multiple active bids on the same asset. For example, in CryptoPunks, Foundation, or SuperRARE, when a bidder outbids the current top bidder, the latter gets automatically refunded. (iv) Bid withdrawal: Some NFTMs, such as CryptoPunks, allow the withdrawal of bids, while others, for example, Foundation, do not. (v) Bid settlement: Bid settlement does not require seller’s intervention in most cases, i.e., the asset automatically goes to the highest bidder. However, for some NFTMs like CryptoPunks, the bid has to be explicitly accepted by the seller.

When an item is sold by a seller other than the creator, it is called a secondary sale. Royalty is the payment made to the creator for every such secondary sale. Before the first (primary) sale takes place, the creator specifies the royalty amount, which is then deducted from every secondary sales and given to the creator. The deduction happens either (i) on-chain, where royalty is calculated by the marketplace contract during the buy transaction, or (ii) off-chain, where the NFTM dApp keeps track of the royalty accumulated from all the sales.

**External entities.** External to both NFTMs and blockchain, there are services and devices that provide the necessary infrastructure for the system to work. For example, creators store their artwork on web servers or storage services such as Amazon S3 or IPFS. When buyers purchase the NFT, they can exercise their bragging right by displaying the art on photobook-style websites or digital NFT photo-frames. The websites, photo-frames, and NFTMs fetch tokens from the blockchain and respective artwork from those services.

### 4 ANALYSIS APPROACH

This paper studies scams, malpractice, and security issues in the NFT ecosystem. In particular, we investigate the following research questions related to the three entities identified in the previous section, i.e., users, marketplaces, and external entities (RQ1.) Are there weaknesses in the way NFTMs operate today, and can those be exploited (Section 5)? (RQ2.) How and to what extent do external entities pose a threat to the NFT ecosystem (Section 6)? (RQ3.) Are users involved in any fraud or malpractice resulting in the financial loss for others (Section 7)?

We used a hybrid (both qualitative and quantitative) approach to answer RQ1, and a quantitative approach for both RQ2 and RQ3. The rest of this section discusses how we collected the data for the quantitative analysis, and we provide a rationale for choosing the specific NFT marketplaces that we examined in more detail.

**Marketplace selection.** In line with previous work [62], we use DappRadar [11], a popular tracker of Dapps, to select the most relevant marketplaces. We selected 8 out of a total of 35 marketplaces.
We provide the details of the collected data in Table 6. To conduct differential analysis for one of the studies, we needed to monitor how the details of certain assets change over a period of time. Therefore, we crawled the same set of assets three times with a three-month interval between two subsequent crawls: in June 2021, September 2021, and finally in December 2021. Moreover, we collected event information continuously between the June and September crawls. We use CoinGecko [6] API to fetch historical prices of the cryptocurrencies to convert the pricing information to their equivalent USD value.

Asset and event information: The first step to collect asset and event information is **asset enumeration**, i.e., obtaining the list of assets traded on a marketplace. Once enumerated, we collect the asset and event information for those assets. For both the steps, we employ three different strategies, subject to marketplace restrictions:

1). **API access:** If a marketplace exposes an appropriate API, we use it to retrieve the list of assets and events. Unfortunately, the APIs are often record-limited, e.g., for a specific query, OpenSea’s API returns at most 10,000 assets. However, the total number of assets listed on their website was 18.2M at the time of crawling. As a workaround, we generate API requests with combinations of sort and filter parameters to fetch different sets of assets with every request.

2). **Web scraping:** If a marketplace does not provide an API interface, but its terms and conditions (T&C) do not disallow scraping of their web interface, we crawl the assets and events data from the website.

3). **Blockchain parsing:** If a marketplace neither provides an API nor allows web scraping, we retrieve asset and event data directly from the blockchain, if possible. Trading activities of a decentralized marketplace are handled by smart contracts that are well-known. Leveraging the ABI (Application Binary Interface) of the contracts published in Etherscan, we parse historical transactions, e.g., `atomicMatch()` in case of OpenSea, to retrieve asset and event details.

Our asset collection is best-effort, as it is impossible to enumerate all the listed assets in a marketplace. This is due to various reasons mentioned above, such as the absence of marketplace APIs, their rate limits, and T&C prohibiting any crawling activity. Table 1 shows the number of assets and events collected for each marketplace, and the strategies used to collect data. Since Nifty does not provide an API, prohibits web scraping through T&C, and stores events off-chain, we were unable to collect data on the marketplace activities.

**Measurement study.** We utilize the asset and event data we collected to perform several measurement studies, which are described in the subsequent sections. We would like to emphasize that we attain reasonable coverage, e.g., OpenSea, the largest NFT that accounts for 89.63% of assets in our dataset, listed 18.2M assets in their website at the time of crawling. We crawled 12.2M assets, which is 66.94% of the size of the marketplace. Since OpenSea contributes to the most number of assets in our dataset, we use only OpenSea in Section 5 (unless the study requires cross-NFTM analysis) and Section 6, as only that dataset would be representative enough to capture the extent of the issues we quantified in those sections. However, since we measured the occurrences of trading malpractices per NFTM in Section 7, we used assets from all the marketplaces. We provide the Ethereum addresses of the major contracts relevant to our study in Appendix D.

### 5 ISSUES IN NFT MARKETPLACES

In this section, we identify weaknesses in the design of NFTMs, which, when abused, pose a significant risk in the form of financial loss to both the marketplaces and its users. For this part of the study, we gathered information from public security incidents, attacks, and abuses reported on various blogs and technical reports, direct interactions with individual marketplaces, and marketplace documentation. We have systematized our findings by connecting those issues with the marketplace activities discussed in Section 3, and then quantified, whenever possible, the prevalence/impact of those issues. Lastly, we systematically evaluated the existence of each of the issues across all the marketplaces (Table 2).

#### 5.1 User Authentication

**Identity verification.** Art in the physical world has been used in money laundering schemes [2]. NFTs might make this process easier, as trades are executed by anonymous users, and there are no physical artworks to be transported. Identity verification is the first step to deter such criminals. Major crypto exchanges, such as Coinbase and Binance US, are highly regulated. To create an account with these exchanges, one needs to provide personally identifiable information (PII), e.g., name, residential address, social security number (SSN), along with supporting documents confirming these details. Without getting the identity verified, it is either impossible to use the platform, or it can only be used with tight financial restrictions in place.

investigate if the NFTMs impose similar regulatory restrictions, we interacted with them by creating accounts. We discovered that no NFTM has made any steps towards enforcing KYC (Know Your Customer) rules nor implemented AML/CFT (Anti-Money Laundering/-Combating the Financing of Terrorism) measures. As a result, apart from being able to hide the identity, a user can create several accounts on the platform that are hard to be traced back to one single entity.

(U2) Two-factor authentication. Enabling 2FA (Two-Factor Authentication) greatly enhances the security of a password-based authentication workflow. While traditional financial institutions like banks, brokerages, and cryptocurrency exchanges, such as COINBASE and BINANCE, provide 2FA as an option, it is not yet a ubiquitous option for NFTMs. SORARE manages a user’s wallet on her behalf. As a result, an attacker who is able to login into an account can download the user’s Ethereum private key associated with the wallet, and transact on behalf of her. Though SORARE does support 2FA, it is not enabled by default. 2FA was also optional for NIfty until the infamous hack [23] that compromised a number of accounts in March 2021. According to their initial assessment, none of the impacted accounts used 2FA when the hack took place.

5.2 Token Minting

(M1) Verifiability of token contracts. A token contract is considered “verifiable” if its source code is submitted to ETHERSCAN. Given the functional complexity of these token contracts, source code is much easier to audit than bytecode. Verifiability of external token contracts is crucial as they can be malicious or buggy. As an example, OpenSea users complained about a malicious token contract that did not transfer tokens after purchase. Also, to make a particular NFT valuable, sometimes NFT projects promise to circulate only a certain number (rarity) of that token. A malicious token contract can be abused to mint more tokens than the rarity threshold, thus dropping the token’s price, which hurts the buyers. A malfunctioning contract can burn gas without even doing any real work, e.g., almost all PurChase events of the CelebrityBreeder contract failed with errors. Ideally, an NFT project should make the source of the underlying token contract available for public scrutiny before the NFTs are minted to make sure that they are neither malicious nor buggy. Unfortunately, none of the NFTMs that support external token contracts mandates such contracts to be open-source.

▶ Quantitative analysis. To enumerate how abundant closed-source NFT tokens are, we queried ETHERSCAN API for every token contract in our dataset to check if its source is present. Out of 11,339 token contracts, 8,122 (71.65%) were open-source, while the remaining 3,217 (28.37%) were closed-source, of which 7,850 (96.65%) and 3,209 (99.75%) tokens belong to OpenSea, respectively.

Further, we intended to evaluate if closed-source tokens are more likely to exhibit malicious behavior than open-source ones. Since NFTMs take down NFTs when they observe or receive a report of either an abuse or a violation of the T&C, we consider “take-down” as an indirect (yet strong) indication of a token being found malicious. According to our observation, 1,765 (55.00%) closed-source tokens were taken down by OpenSea between June and December, which account for $328.8M USD in trading volume. On the contrary, only 606 (7.72%) open-source tokens were taken down during the same span.

(M2) Tampering with token metadata. The metadata of a token holds the pointer to the corresponding asset. Hence, if the metadata changes, the token loses its significance. The ERC-721 standard for NFTs actually allows for the possibility to change a token’s metadata. However, when an NFT represents a particular asset (such as a piece of art) that is sold, changing the metadata violates the expectation of the buyer. The location and the content of the metadata are decided at the time of minting. A malicious creator/owner A can alter the metadata by manipulating either of the two post-minting: (i) by changing the metadata of asset 1, and (ii) by modifying the metadata itself. Even if (i) can be disabled at the contract level, metadata hosted on third-party (web) domains can be freely modified by A, if she controls the domain. This second attack can be prevented if the metadata is hosted in IPFS. Since the URL of an object stored in IPFS includes the hash of its content, the metadata cannot be modified while retaining the same URL recorded in the NFT.

For internal token contracts, CRYPTOPIKNS, FOUNDATION, RABLE, and NIifty offer no way to update metadata of an NFT. AXIE allows the creator to modify the URL at any time. OPENSEA, SUPERREAR, and SORARE allow modification by the creator until the first sale. Since only FOUNDATION mandates storing the metadata on IPFS, other NFTMs are susceptible to the second attack for the internal contracts. Since no NFTM supporting external token contracts employs any check to prevent metadata tampering, both attacks are feasible.

▶ Quantitative analysis. We performed a differential analysis to determine the change in the metadata URL of external assets over a period of time. Specifically, we monitored the metadata URL of all 9,064,767 external OPENSEA assets three times over a span of six months in an uniform interval—in June 2021, September 2021, and December 2021, respectively. Since ERC-721 metadata extensions are optional (explained in Section 6), metadata URLS were completely missing for some of the assets. Also, OPENSEA took down some assets during this time period, which is why their metadata URL could not be retrieved in the subsequent crawl. After excluding these two kinds of assets, we were left with 3,079,139 assets that had metadata URLS in all three crawls. According to our observation, the metadata URLS of 89,089 (2.89%) and 35,446 (1.15%) assets changed between the first two and the last two crawls, respectively.

5.3 Token Listing

(L1) Principle of least privilege. While listing an NFT, the NFTM takes control of the token so that when a sale is executed, it can transfer the ownership of the NFT from the seller to the buyer. To this end, the NFTM needs to be either (i) the owner of the NFT: that is, the current owner transfers the asset to an escrow account E during listing, or (ii) a controller: an Ethereum account C that can manage that specific NFT on behalf of the owner, or (iii) an operator: an Ethereum account O that can manage all the NFTs in that collection. The escrow model in case (i) is risky because one single escrow contract/wallet E managed by the NFTM holds all assets being traded on the platform. Therefore, the security of all assets in a marketplace depends on the security of the escrow contract or the external account that manages such contract. This design essentially violates the principle of least privilege. As a result, either a vulnerability in the contract or a leak of the private key of the external account could compromise the security of all the stored NFTs. NIfty,
While displaying an NFT on sale, invalid caching could trick a buyer into purchasing an NFT for which the asset is either non-existent or different from what the NFTM displays using its stale cache.

**Quantitative analysis.** Among the NFTMs in our dataset, Foundation holds tokens in an escrow contract, while Nifty uses an Externally Owned Account (EOA) as escrow wallet. SuperRare escrows tokens only when an auction is ongoing. The larger the number of NFTs held in escrow, the greater is the risk. On December 31, 2021, SuperRare, Foundation and Nifty held 55,64079, and 90988 NFTs in their escrow accounts, respectively. In Appendix A, we show how the number of escrowed NFTs increased over time for both NFTMs.

**L(2) Invalid caching.** While displaying an NFT on sale, OpenSea and Rarible leverage a local caching layer to avoid repeated requests to fetch the associated images. If the image is updated, or disappears, the cache goes out of sync. This could trick a buyer into purchasing an NFT with the asset appearing visually indistinguishable from the verified ones at a cursory glance. (ii) Impersonation. Abusing weak verification procedures, scammers got their fake profiles verified by just submitting social media handles, without actually proving the ownership of the corresponding accounts [32]. (iii) Wash trading. One of the requirements of OpenSea to verify a collection is to have at least 100 ETH in trading volume [24], which is possibly hard to attain for a newly launched collection. Historically, this requirement has incentivized people to perform wash trading, i.e., performing fictitious trades between multiple accounts that are all under the control of the attacker, to artificially inflate sales volumes.

**Quantitative analysis.** To highlight the economic incentive behind verification abuse, we present the number of sales and the sales volume generated by the verified and non-verified sellers and collections in OpenSea in Table 3. Though only 0.40% sellers and 0.77% collections of OpenSea are verified, the average sales per verified seller and collection are 10 and 1,059 times more than their non-verified counterparts, respectively.

Next, we measure how effective the NFTM verification mechanisms are in preventing abuse. Had the verification mechanism been foolproof, then a verified collection could not be malicious, and in turn, it should never have been taken down. However, we observed that 4.88% of the verified and 4.78% of the non-verified OpenSea collections were taken down in six months (between June and December 2021). This indicates that though verification attempts to reduce abuse, it fails to eliminate it completely. The fact that the verified collections are still taken down shows that bad actors do “slip through” the system and verify their collections.

### 5.4 Token Trading

**(T1) Lack of transparency.** NFTs are asset-ownership records that should be stored on the blockchain to allow for public verifiability. In a decentralized setting, an NFT sale is handled by a marketplace contract \( C_m \) that invokes the transfer() API of the token contract \( C_t \) to transfer the token from the seller to the buyer. Every sale transaction and the associated transfer, for example, the atomicMatch() call in case of OpenSea, is visible on the blockchain. Among other things, each transaction includes the following information: (i) address of the seller (current owner), (ii) address of the buyer (new owner), (iii) how much the NFT was sold for, (iv) time of ownership transfer. Querying for ownership has further been made easier by ERC-721 ownerOf() API that returns the current owner of a token. The sales records, in conjunction with the API, permit one to reconstruct the precise sales and ownership history of an NFT.

On the other hand, if sales records and transactions are stored off-chain, it becomes impossible to verify any trades and the ownership history of an NFT. Moreover, a malicious NFTM can abuse this fact to forge spurious sales records to inflate the trading activity and volume. Off-chain records are susceptible to tampering, censorship, and probably disappear if the NFTM database goes down. Among the NFTMs we surveyed, only Nifty maintains off-chain records. When an item is listed, Nifty takes control of the NFT by first having it transferred (\( T_1 \)) to an escrow wallet. Thereafter, multiple trades can take place while Nifty holds the custody of the asset, but no sales record is ever emitted on the blockchain. If and when the owner decides to take the NFT out of Nifty, the marketplace transfers (\( T_2 \)) the token back to the

(T2) Fairness in bidding. NFTMs implement bidding either (i) on-chain, through a smart contract that requires the bid amounts to be deposited while placing the bid, or (ii) off-chain, through the NFTM dApp which maintains an orderbook without requiring any upfront payment. Off-chain bidding is unfair as it can be abused by both the NFTM and the users. Since bids are not visible from the blockchain, NFTMs can inflate the bid volume to create hype. Also, placing bids is inexpensive, as there is no money transfer involved. Therefore, such NFTMs are more susceptible to bid pollution, a form of abuse where a large number of casual bids are placed on items. Since no money is locked, most of these bids are likely to fail due to a shortage of funds in the bidder’s account at the time of execution. Since on-chain bidding costs gas to place/cancel bids, it deters scammers from placing spurious bids, making abuses less frequent. Moreover, on-chain bids reserve the bid amount upfront. Therefore, such bids invariably succeed during settlement. In OpenSea, we observed sellers complain that (attempted) sales of their items fail because the WETH balances of the winning bidders drop below the offered amounts.

▶ Quantitative analysis. Unless a bid fails due to lack of funds, an NFT gets transferred to the highest bidder at the end of the auction. To measure the extent of bid pollution in the NFTMs, we enumerated the auctions where the highest bidder did not receive the item. This is unfair to the seller, because the bid immediately below might be a lowball offer. Our analysis uncovered 16,215 and 15,368 such instances out of 48,862 and 19,109 total auctions in OpenSea and Rarible, respectively. We did not find any evidence of the same in the Foundation, Axie, and SuperRare marketplaces.

(T3) Royalty distribution and marketplace fee evasion. If a royalty is set, every trade should earn a fee for the creator. However, we identified ways in which users can potentially abuse the royalty implementations: (i) Cross-platform. As explained in Section 3, royalty is enforced by either the marketplace contract or the dApp, both of which are specific to an NFTM. Also, NFTMs do not share royalty information with each other. Therefore, royalty set on one platform is not visible from the other. Leveraging this lack of coordination, a malicious seller can evade royalty by trading the NFT through a platform where royalty is not set, though it is set on another. (ii) Non-enforcement. Neither royalty nor marketplace fees are enforced in ERC-721 token contracts. A malicious seller can thus avoid both payments by transferring (ERC-721 transfer()) the NFT to the buyer directly and settling the payment off-platform. Both royalty and fees could be levied inside the transfer method of the token contract, though the additional logic makes the API more expensive. (iii) Post-sales modification. OpenSea and Rarible allow the creator to modify the royalty amount even after the primary sale. Now, the royalty is calculated on the price listed by the seller. In a potential abuse scenario, a creator can first lure a buyer B by setting a low royalty and then increasing it post-sales. During secondary sales, B may not notice this change at all, and may end up giving more royalty to the creator than initially advertised.

▶ Quantitative analysis. We discovered potential abuses of unconditional token transfer (case ii) to evade NFTM fees and royalty. The question of evasion appears when a seller S lists an NFT on a marketplace to gain popularity, but executes the trade off-platform, entirely bypassing the marketplace protocol. There could be two possible cases. Seller S might trust the buyer B and, therefore, transfers the NFT first. After that, B settles the payment. In the other case, the order is reversed. For the assets listed in each NFTM, we counted the number of occurrences on the blockchain where an address (seller) S transferred the NFT to another address (buyer) B, and B sent a payment to S on-chain within 15 minutes (before or after) the transfer transaction. We found 56920, 302, 2777, 5, 814, 56, and 0 such instances for assets listed in OpenSea, SuperRare, Rarible, Foundation, CryptoPunks, Sorare, and Axie, respectively. Note that this estimate is conservative, because the payment could be made either off-chain or outside the time window that we considered for our analysis.

We also measured how often creators abuse sellers by increasing the royalty after the primary sale (case iii). For each OpenSea asset, we enumerated the “sell” events in increasing order of time, and counted the number of times the royalty was increased with respect to the previous sale. We discovered 157,450 instances of such royalty modifications across 20,802 (8.81%) collections.

6 ISSUES RELATED TO EXTERNAL ENTITIES

The asset (picture, video) that an NFT points to must be accessible for this NFT to be “meaningful.” NFTs can point to assets in two ways. If the nft contract is ERC-721-compliant and implements the metadata extension, then the token includes a metadata_url on-chain, which points to a metadata record (JSON). This record, in turn, includes an image_url field that points to the actual digital asset. Many older tokens, on the other hand, are not standard-compliant and do not contain any on-chain image_url. Instead, they use some ad-hoc, off-chain scheme to link to an asset. For such NFTs, NFTMs implement custom support so that they can generate valid image URLs. Since both the metadata record and the asset are stored off-chain, those do not enjoy the same guarantee of immutability as the NFT itself. When any URL becomes inaccessible, that breaks the link between the NFT and the corresponding asset. In practice, the URLs frequently point to a distributed storage service, e.g., IPFS, or centralized storage, e.g., a web-domain or Amazon S3 bucket. For IPFS URLs, if the NFT owner is aware, she can keep the NFT “alive” by pinning the resource (i.e., storing it persistently). Even that could also be problematic, because NFTs do not store the hash value of the actual resource but rather store URLs that point to an IPFS gateway web service. If the gateway becomes unavailable, the NFT “breaks.” In general, NFTs that include non-empty image_url fields. The remaining 3,860,607 assets did not have an image_url field, which means that they are hosted directly on OpenSea (content creators have the option to leave the image URL field empty, in which case OpenSea handles the hosting). We first check whether the image and metadata URLs point to resources hosted on IPFS. Next, we check whether the URLs are still accessible. To this end, we perform an HTTP HEAD query. If the query returns with a response code other than 200 (OK), we perform an HTTP GET
query next. If that also returns a non-200 response code, we mark that URL as inaccessible. We take this two-step approach to optimize for performance, and not to generate false negatives due to web servers that do not respect HEAD queries. Also, the servers hosting the assets could be offline at the time of testing, but later come back up online. To account for this possibility, we repeated the above URL-check three times in a span of 15 days. Only the assets marked as inaccessible in the previous attempt were tested for accessibility each time. An asset is finally marked as inaccessible only if all three attempts agree.

Figure 3 reports our findings. Two important observations are: (i) Only 3.91% of the assets (images) and 9.04% of metadata records hosted on IPFS have disappeared in our dataset between June and December; as expected, NFTs hosted on IPFS are less likely to disappear than those hosted on non-IPFS domains. (ii) Though IPFS is supposed to be more resilient to disappearance of the assets, a majority of asset URLs (88.71%) as well as metadata URLs (80.69%) are hosted on non-IPFS domains. Looking at all lost NFTs, they have generated a staggering amount of $160,761,805 USD in revenue from 118,294 transactions. Not only that, due to the caching issue we discussed in Section 5, it is very well possible that a fraction of them are still in circulation. As this analysis shows, persistence is a pressing issue in the NFT space.

7 FRAUDULENT USER BEHAVIORS

In this section, we study the impact of various fraudulent user activities that occur in NFTMs. In particular, we look at counterfeit NFT creation as well as trading malpractices, such as wash trading, shill bidding, and bid shielding. In Appendix E, we then cover a few more types of malicious activities that were reported in blogs and articles.

7.1 Counterfeit NFT Creation

The authenticity of an NFT is endorsed by the smart contract managing the collection. Therefore, to ensure that the token is one being bought is legitimate, buyers are advised to verify the contract address of the collection from official sources, e.g., the project’s web page, before making a purchase. Unfortunately, buyers are not always aware of the existence of counterfeits, or of how they can verify an NFT’s authenticity. Instead, they only rely on the names and visual appearances of items in the marketplaces. This makes it possible for malicious users to offer “fake” NFTs. We observed the following types of counterfeits:

(i) Similar collection names. There are fake NFTs that use the name of a collection or individual piece that resembles the original (victim) one. A common trick is to substitute ASCII characters in the original name with non-ASCII characters that look alike. To prevent such abuse, OpenSea restricts users from using popular collection names and certain special characters. Still, it is often possible to circumvent these limitations, e.g., by adding a dot(·) at the end of the name or substituting an upper-case character with a lower-case one, e.g., a fake of “CryptoPunks” collection used the name “Cryptopuzzles.” Moreover, restrictions can cause problems for legitimate users, e.g., French users complained about not being able to use the accented characters in collections.

(ii) Identical image URLs. Some fake NFTs point to existing assets, i.e., they simply copy the image_urls of legitimate NFTs. For example, CryptoPunks is a well-known collection. Of course, nothing prevents a scammer from deploying her own token contract on the blockchain and mint tokens that point to CryptoPunks. A buyer who just looks at the appearance of items in a collection will see the CryptoPunks images and might mistake the NFTs for the originals.

(iii) Similar images. Instead of copying the image_url, a scammer might copy the digital asset and then mint an NFT that points to this copy. As of now, no NFTM runs any similarity check to detect if a media file has already been used by other NFTs.

Quantitative analysis. We looked for each type of counterfeits present in the OpenSea dataset comprising of 12,215,650 NFTs spread across 236,037 collections.

(i) To check for (potential) counterfeits that abuse similar collection names, we compute the Levenshtein distance, an edit distance metric between pairs of collection names (strings). Since a shorter distance indicates greater similarity, we considered a maximum distance of 2 characters, which means that we only consider collection names as similar if they differ in at most two characters. We considered 52,399 collections that have names longer than 7 characters, and a minimum of 10 NFTs in it (collections with fewer NFTs could be insignificant) to avoid spurious matches. Given that it is more beneficial to imitate verified collections, we only considered collection pairs that include one verified collection (and the other one is considered to be its replica).

Our analysis found 322 collection pairs with similar names. We noticed that the names of most of the replica collections were minor modifications of the names of the respective verified collections, for example, pluralizing a noun, adding whitespace at hard-to-notice positions, etc., which indicates a potential intent to mislead. We then randomly picked 100 pairs and checked if those replica collections indeed contain images that are similar to the verified ones and that could mislead buyers. Since judging the similarity visually could be subjective, two researchers independently performed the assessment, and a pair was marked “visually similar” only if both the decisions agreed. We discovered 11 such collections, which we reported to OpenSea requesting a take-down. Moreover, we identified an additional 11 collections that were already taken down by OpenSea (which indicates wrongdoing) between June and December 2021.

(ii) To check for counterfeits that leverage identical image_urls, we first collected 8,363,550 image_urls comprising of 944,420 IPFS, and 7,419,130 non-IPFS URLs from our dataset. Objects on IPFS are accessed through IPFS gateways, which are web services. An IPFS URL is typically of the form: http(s)://<gateway>/<ipfs_hash>. Any gateway can be used to access the object pointed to by <ipfs_hash>. Therefore, we pre-processed those URLs to extract only the hash component. In the last step, we performed a string comparison between every pair of IPFS hashes and non-IPFS URLs, which reported
356,377 and 2,082,119 identical IPFS, and non-IPFS URLs with at least one duplicate, respectively.

(iii) To find potential counterfeits due to image similarity, we crawled the images pointed by the `image_url` for all NFTs in our dataset. Since the individual assets linked to NFTs can be very large, we decided to focus on downloading just the smaller resolution version of an asset generated and cached by OpenSea. We then used the perceptual algorithm [36] of ImageHash [26], a popular (2.1K GitHub stars) image hashing tool, to compute a “fuzzy” hash that is tolerant to small perturbations of the images. Lastly, we compare every pair of hashes to find similar images. We refrain from comparing hashes of the images that are part of the same collection, as they are likely similar (but not counterfeits). We downloaded 9,991,013 images, and we discovered 59,425 hash collision pairs. We randomly picked 100 such pairs, and manually verified that 90% of those image pairs are indeed visually identical.

### 7.2 Trading Malpractices

In this section, we explore illicit trading practices, specifically, wash trading, shill bidding, and bid shielding [4, 43, 47]. We first discuss how these malpractices are relevant in the context of NFTMs, and then build heuristic models to detect such attacks. Finally, we apply these models to all 13,628,411 assets and 354,355,763 events we collected (Section 4). The goal is to measure the extent and impact of these trading activities on the top 7 NFTMs.

#### Data modeling.

From the event data and the Ether flows collected from blockchain transactions, we extract actions (such as transfers, sales, bids, ...) that operate on NFTs. Figure 7 shows the types of predicates (actions) that we record for users u, assets a, auctions id and prices p. These predicates capture relationships that we use to build four different graphs: A sales graph $G_s$ (sale), a bidding graph $G_b$ (auction, bid, cancel, bid, win), a payment graph $G_p$ (paid), and an asset transfer graph $G_t$ (transfer). $G_s$ contains two types of nodes: users (u) and assets (a), and directed edges from u to a annotated with property tuples of the form (p, t, i). All of $G_s$, $G_p$, and $G_t$ contain only one type of node: users (u), and directed edges from $u_1$ to $u_2$. Edges in $G_s$, $G_p$, and $G_t$ are annotated with property tuples of the form (a, p, t), (e), and (a), respectively.

#### 7.2.1 Washing Trading.

In wash trading, the buyer and the seller collude to artificially inflate the trading volume of an asset by engaging in spurious trading activities. In NFTMs, users wash trade to either create the illusion of demand for a specific asset, artist, etc., or to inflate metrics that are of their financial interest, such as getting a profile/asset verified, or collecting rewards. For example, Rarible users are incentivized by SRAI governance tokens where the more a user spends, the more tokens they receive [29]. It is suspected that many high-value NFT sales related to popular projects such as CryptoKitties [7] and Decentraland [12] are instances of wash trading [47].

#### Detection.

In the NFT space, wash traders primarily intend to increase the sales volume of NFT collections. To detect wash trading, given a set of assets $A = \{a_1, a_2, ..., a_n\}$ that are part of a collection, we check for a set of users (addresses) $U = \{u_1, u_2, ..., u_m\}$ who heavily trade those assets with each other. We assume a limited number of colluding users to make the problem tractable (we use an empirical threshold of 50 users). In other to generate wash trades, these users repeatedly trade that set of assets among them, which often results in cycles in the sales graph $G_s$. Hence, we check $G_t$ for the existence of cyclic relationships among these users. In a strongly connected component (SCC) of a graph, there exist paths between all pairs of vertices. Therefore, this type of wash trade can be detected [70] by checking if two users $u_1$ and $u_2$ appear in any SCC of the sales graph $G_s$. In other words, if SCC($u_1, u_2, G_s$) holds, it means that both the users are involved in round-trip trades, i.e., there exist either direct, or indirect sale relations between them in both the directions. Now, two users being a part of an SCC can be accidental, and does not indicate the frequency of trades between them. However, in a wash trade, users are involved in frequent sales. Therefore, we only consider SCCs where the number of sale relationships between every two intermediate users is above (indicating ‘heavy’ trading volume) an empirically determined threshold ($\epsilon$). We used $\epsilon = 10$ in our analysis.

However, bad actors can come up with more intricate strategies to conceal apparent connections so that such simple detection can be evaded. We manually analyzed the blockchain transactions history and found two evasion strategies that would throw off the prior analysis. In the first case, when we investigated an otherwise legitimate-looking sale relation $u_1 \rightarrow u_2 \rightarrow u_3$, we realized that both $u_2$ and $u_3$ are funded (Ether transfer) by the same “parent” user $u_1$. We capture this case by checking if two users: $u_1$ and $u_2$ appear in any weakly connected component (WCC) of the payment graph $G_p$. In other words, if WCC($u_1, u_2, G_p$) holds, it means that direct or indirect Ether-flow exists between those two users in either direction. In the second case, for a sale relation $u_1 \rightarrow u_2 \rightarrow u_3$, we identified multiple unconditional asset transfers (ERC-721 transfer()) from $u_1$ to $u_3$, giving a strong indication of a close tie between those users. We capture this case by checking if two users: $u_1$ and $u_2$ appear in any WCC of the transfer graph $G_t$. In other words, if WCC($u_1, u_2, G_t$) holds, it means that direct or indirect unconditional asset transfer relationships exist between those two users in either direction.

To summarize, our model considers any sale($u_{1,....,u_{2}}$) relation a potential wash trade if: $\text{SCC}(u_1, u_2, G_s) \lor \text{WCC}(u_1, u_2, G_p) \lor \text{WCC}(u_1, u_2, G_t)$.

#### Quantitative analysis.

We extracted 9,393 instances of wash trading that generated $96,858,093 USD in trading volume across 5,297 collections involving 17,821 users in all NFTMs except AXIE, FOUNDATION, and CryptoPunks. Moreover, out of 238,180 collections in our dataset, only 8,869 collections had more than $2K in trading volume, out of which 2,569 (28.97%) collections show signs of wash trading.

We define $\text{wash\_trade\_factor}$ (WTF) as the fraction of the total trading volume of a collection generated by wash trading, i.e., if WT$F$ is 1, then all the trades are wash trades. In Figure 4, we show the distribution of the $\text{wash\_trade\_factor}$ across collections where wash trading has been detected. Of all the wash traded collections, $1,824$ (34.43%) had less than 5% ($\text{WT}F$ < 0.05) of the trades generated by wash trades. Interestingly, we discovered $1,571$ (29.66%) collections which were heavily abused, because more than 95% of all of their trades are wash trades, totaling $3,407,284 USD$ in the trading volume. Figure 5 shows the relative volumes of wash trades that have happened in different NFTMs. Though nearly equal volume of wash trades were discovered in both Rarible (49.30%) and OpenSea (50.43%), given that the overall trading volume of OpenSea is 21 times more than that of Rarible, it seems that wash trading is significantly more frequent in Rarible than OpenSea. Our finding
is also corroborated by discussions we saw on Rarible Discord, which indicates a heavy amount of past wash trading incidents as malicious users attempted to secure $RARI tokens.

**Manual analysis.** In our analysis, the size of a connected component represents the number of addresses involved in a wash trade. We observed that 98.88% (9,288 of 9,393) of the reports had a component size at most 10. Therefore, for our manual analysis, we randomly selected 100 reports, and checked whether one of the following two conditions holds: (i) if a user addresses are involved in a transactions on n NFTs, then both t ≥ 2d and n ≪ t need to hold. The intuition is that if a set of users “heavily” trades on only a small number of assets, then those are likely to be wash trades. Alternatively, (ii) the addresses involved in trading are all funded by a common, on-chain funding source. This is true when the “supposed” buyers, in reality, are all funded directly by the seller, or by a seller-controlled address, before making (pseudo) purchases. If one of these two conditions holds, we consider a detected wash trade instance as a true positive. We determined all the sampled instances as true positives.

**Limitation.** Ethereum mixers (informally “tumblers”), such as Bitmix [5], ETH Mixer [17], and Tornado Cash [45], are anonymity services that help to conceal the true source of a payment by breaking the link between the receivers and the sender of the funds. Specifically, these services accept Ethers from a user, and either route it to a smart contract, or relay it through a complex, large network of addresses by splitting the amount into a number of micro-transactions; essentially mingling that fund with hundreds of other users. Since our wash trade detection strategy leverages information about Ether flows between two addresses, mixers can lead to false negatives.

7.2.2 Shill Bidding. Shill bidding is a common auction fraud where a seller artificially inflates the final price of an asset either by placing bids on her own asset, or colluding with other bidders for placing spurious bids with increasingly higher bid amounts. This can lead to honest bidders paying higher prices than they would have otherwise. With high-value bids on assets becoming increasingly common, it is suspected that many sales suffer from artificial price inflation [43].

**Detection.** Detecting shill bidding is difficult when looking at a single auction in isolation. It becomes even harder when malicious users take turns, placing bids on each others’ auctions so that the seller–bidder relation changes. In this paper, we only consider the simple case where a specific user repeatedly places bids in auctions, yet, never (or rarely) purchases anything. Moreover, we check whether there is some relationship between this user and the seller. Thus, our findings should be viewed as a lower bound on the actual number of shill bidding occurrences in NFTMs. Our detection mechanism draws on our insight from the manual analysis of NFTM activities and prior work [68].

Let bid(u, p, t, id, a) denote the i-th bid placed by user u with amount p at time t on asset a in an auction with id created by the seller. Then, user u is a shill bidder if:

**Rule 1.** u placed at least n bids on an asset a auctioned by u, with monotonically increasing bid amounts. That is, ∀i ∈ [1, n], bid(u, p, t, id, a), the following holds: ∀i ∀j, t, t > t ⇒ p, p.

**Rule 2.** u never buys the asset a, i.e., win(u, p, t, id, a) is false.

**Rule 3.** u has limited buying/selling activity, i.e., |{sale(u, p, t, id, a)}| < σ, where σ is an empirically determined threshold. We set σ = 10 for our analysis.

**Rule 4.** u is “connected” to the seller u, either through Etherflows (G_p) or asset transfers (G_t). That is, WCC(u, u, G_p) ∨ WCC(u, u, G_t) holds.

**Rule 5.** We define shill score as the ratio of the number of times u participates in an auction created by u and the total number of auctions that u participated in. In our detection approach, the shill score must be greater than μ another empirically determined threshold. We set μ = 0.8 for our analysis.

**Quantitative analysis.** We detected 703 instances of shill bidding across 282 collections involving 1,211 users in all NFTMs except AXIE and CRYPTOPIKNS. We estimate shill profit as the profit made by the seller due to shill bidding. Specifically, assume legitimate bidders place bids on an item first, and then shill bidding drives the price up.
The item was targeted by a shill bidder who bid on the item, thereby making the item finally sell at $24,519.27 USD, the maximum was as high as $152,606.31 USD for one of the tokens in Mirandus Vaults, a verified collection. Additionally, all 316 instances together shielded a total of $942,061 USD worth of bids.

Figure 8 shows the number of instances of bid shielding discovered across collections where bid shielding has been detected. For most of the collections (113 out of 117), we find less than ten instances of bid shielding per collection. Ethereum Name Service (ENS), a popular Ethereum name lookup service, makes it to the top of the list with 49 bid shielding instances. Another notable finding in this category was the CryptoVoxels collection. We noticed several complaints by CryptoVoxels collectors on their Discord server about the recent increase of bid shielding activity. According to our analysis, $24,519.27 USD worth of bids were shielded by 35 instances of bid shielding, which corroborates this prior observation. Our results show that bid shielding is frequent in verified collections as 66.67% (78 out of 117) of the bid shielded collections were verified.

- **Manual analysis.** We have manually verified randomly chosen 100 instances flagged by our analysis. During manual analysis, we mark an instance as a true positive if (i) the potential bid shielder B and the (colluding) auction winner W are the last two highest bidders on that auction in that order, and (ii) B cancels her bid just before (≤ 2h) the auction ends, and (iii) during the auction, they never outbid each other. Out of the 100 instances, our manual analysis confirms 90 such instances as true positives. Our detection model produced some false positives because it does not take into account the last condition listed above. Let \(b_i\) and \(w_j\) be the bids from B and W, respectively. Now, first they outbid each other, i.e., \(b_1 \rightarrow w_1 \rightarrow b_2 \rightarrow w_2 \rightarrow b_3\), and then B moves \(b_3\) at the last moment (possibly B just changes her mind). This is not a bid shielding scenario, as the bids from B drove up the price for W. This would not happen in a bid shielding scenario as B and W are colluding. However, the first two conditions are still met, and therefore our model incorrectly flags this case. We also observed that most of bid shielding activities are performed in verified collections, such as CryptoVoxels, ENS, etc., as they are popular and in high demand.

### 7.2.3 Bid Shielding

In bid shielding, a malicious bidder \(u_2\) guards a low bid, possibly from a colluding bidder \(u_1\), with a bid high enough to deter legitimate bidders from placing any additional bids. Immediately before the auction ends, \(u_2\) retracts the bid, thus uncovering the low bid from \(u_1\) to let her win the auction.

**Definition.** We apply the following heuristics to detect instances of bid shielding in NFTs. If for two users \(u_1\) and \(u_2\), bid \((u_1, p_1, t_1, id, a)\) or \((u_2, p_2, t_2, id, a)\) and cancel bid \((u_2, p_2, t_3, id, a)\), then \(u_2\) is shielding a bid from \(u_1\) if:

- **Rule 1.** For all bids \((u_1, p_1, t_1, id, a)\), placed on asset \(a\), \(t_3 > t_1\) holds, i.e., no new bid was placed after \(u_2\) retracted her bid on asset \(a\).

**Rule 2.** \(u_1\) won the auction with id id. That is, \(\text{win}(u_1, p_1, t_4, id, a)\) holds, and \(u_1 \neq u_2 \land p_1 < p_2\).

#### Quantitative analysis.

We detected a total 316 instances of bid shielding across 117 collections involving 471 users only in OpenSea. It is expected, because other NFTMs implement bidding policies (Section 3) to deter such malpractices, for example, on-chain bids, removal of the the previous bid when outbid, etc. We compute \(\text{shielded\_bid\_difference}\), the difference in the bid amounts of the two colluding parties, the potential bid shielder and the auction winner. While the minimum \(\text{shielded\_bid\_difference}\) amount was $209.77 USD, the maximum was as high as $152,606.31 USD for one of the tokens in Mirandus Vaults, a verified collection. Additionally, all 316 instances together shielded a total of $942,061 USD worth of bids.

- **Manual analysis.** We have manually verified randomly chosen 100 instances flagged by our analysis. During manual analysis, we mark an instance as a true positive if (i) the potential bid shielder \(B\) and (the colluding) auction winner \(W\) are the last two highest bidders on that auction in that order, and (ii) \(B\) cancels her bid just before (≤ 2h) the auction ends, and (iii) during the auction, they never outbid each other. Out of the 100 instances, our manual analysis confirms 90 such instances as true positives. Our detection model produced some false positives because it does not take into account the last condition listed above. Let \(b_i\) and \(w_j\) be the bids from \(B\) and \(W\), respectively. Now, first they outbid each other, i.e., \(b_1 \rightarrow w_1 \rightarrow b_2 \rightarrow w_2 \rightarrow b_3\), and then \(B\) moves \(b_3\) at the last moment (possibly \(B\) just changes her mind). This is not a bid shielding scenario, as the bids from \(B\) drove up the price for \(W\). This would not happen in a bid shielding scenario as \(B\) and \(W\) are colluding. However, the first two conditions are still met, and therefore our model incorrectly flags this case. We also observed that most of bid shielding activities are performed in verified collections, such as CryptoVoxels, ENS, etc., as they are popular and in high demand.

### 8 RELATED WORK

To the best of our knowledge, we are the first to perform an in-depth study of security and privacy risks in the NFT ecosystem. Our paper fits into the recent line of work on cryptoeconomic attacks in decentralized finance (DeFi) systems. The transparency of blockchains opens up the possibility of launching economic attacks by manipulating the market. Since uncommitted Ethereum transactions and their gas bids are visible to other network participants, an attacker can offer a higher gas price to get their malicious transactions mined early in a block, before the victim transaction. This behavior is called front-running [54]. The authors in FlashBoys [52] demonstrated how...
arbitrage bots front-run transactions in decentralized exchanges (DEX) to generate non-trivial revenues. Sandwich attacks take this idea a step further by both front- and back-running victim transactions. Zhou et al. [76] quantified the probability of being able to perform such an attack and the profits it can yield. In fact, a recent paper [66] reported the profit extracted from the blockchain to be a staggering $28.8M USD in just two years, leveraging sandwiching, liquidation, and arbitrage. The authors also measured the prevalence of other profit-making operations, e.g., clogging and private mining. Another DeFi trading instrument, flashloans, allows a borrower immediate access to a large amount of funds without offering any collateral, under the condition that the loan needs to be repaid in the same transaction. Qin et al. [67] analyzed how flashloans have been used to execute arbitrage and oracle manipulation attacks, and they presented a constrained optimization framework to cleverly choose the attack parameters that maximize the profit. DeFiPoser [75] proposes trading algorithms to generate profit by crafting complex DeFi transactions, both with and without flashloans. Recent research [56, 61, 73] has also characterized and quantified pump-and-dump, a price manipulation scheme that attempts to inflate the price of a crypto asset by spreading rumors and misinformation.

9 CONCLUSION

This paper conducts the first systematic study of the emerging NFT ecosystem on 8 top NFT marketplaces (NFTM). First, we perform a large-scale data collection from various sources, viz., Ethereum mainnet, NFTM websites, and their documentation. We compile a comprehensive list of design weaknesses originating from the NFTMs and external entities, which often lead to financial consequences. Further, we develop models to detect common trading malpractices, and quantify their prevalence in these marketplaces.

REFERENCES

observations with regards to the corresponding sales transactions. Note that collecting information about our high-profile NFT sales was challenging since as is no source of ground truth. We primarily utilized four main sources: (a) search engines, (b) hashtag search in Twitter, (c) searches on Reddit, and (d) the blockchain.

B.1 Desirable properties of the ecosystem.

Since NFTs are built around cryptocurrency and blockchain, it is not unfair to expect the ecosystem to draw on the benefits offered by those technologies. We identify the following properties that an NFTM protocol must hold in order to set it apart from traditional e-commerce platforms like Amazon, eBay, etc. In other words, an NFTM that lacks in one or more of the following benefits should be deemed less valuable as a new platform—(P1) Decentralization. NFTs should be stored on blockchain to ensure persistence, censorship-resistance, immutability, and public verifiability of the asset-ownership record. Keeping verifiability in mind, ERC-721 standard offers the ownerOf() API which returns the address of the current owner given a _tokenId. Since transfer events alter the ownership of an NFT, all those events should be recorded on-chain for an NFT to be verifiable. Blockchain transaction history allows one to track when the NFT was created, who the previous owners were, and
how much it was traded for each time. If an NFTM protocol escrows a token to a wallet \(W\), no sale record is emitted on the blockchain, except the one where the current owner withdraws the token from \(W\) to her own wallet. Such a model makes the token opaque and unverifiable. Also, as opposed to blockchain, if the ownership record is stored in a centralized database, it is susceptible to tampering, censorship, and prone to disappear if the database goes away. An NFTM protocol should not sacrifice any of these guarantees in its design.

(P2) Crypto payment. The payment toward the NFT trade must be made in cryptocurrency, e.g., a primary token like Ether (ETH), or a secondary token like Wrapped Ether (WETH), etc. (P3) Trustless trading. The trade must happen in a trustless manner, without relying on a third-party \(T\) (other than the buyer \(B\) and the seller \(S\)) who mediates either the transfer of assets or the payment. For example, a protocol where \(T\) escrows the token from \(S\), accepts the payment from \(B\), and then exchanges the token and the payment—beats the very purpose of decentralization by making the parties put trust on \(T\).

(P4) Atomic swap. The transfer of assets and the Crypto payment must take place in the same transaction in an atomic manner, i.e., either both succeed, or both fail. Atomicity enables two mutually distrustful parties to get involved in a trade without risking losing the asset or the funds. (P5) Token minting. A token has to be minted before or at the time of sales (e.g., lazy-minting), but not after. This must hold because, in a trustless setting, an NFT cannot technically be sold, or transferred, unless it exists when the trade is executed.

B.2 Analysis of top sales

In Table 4, we consolidate the sales information available in the public domain. As can be seen, at least half of the sales in Table 4 violate one or more of our desirable properties. We indicate the principle(s) a specific sale violates inside the parentheses.

For Beeple’s Everydays, the highest valued ($69.3M) sale, we found the ownership transfer record on the blockchain. However, payment is not present (P4). In other words, we failed to find any evidence that $69.3M was indeed transferred from MetaKovan (the buyer) to Beeple (the artist and seller).

For the second-largest transaction, several tweets [8, 9] indicated that CryptoPunk #7523 was sold on June 10, 2021. However, the actual transfer on the blockchain took place more than a month later (July 15, 2021) (P4). Moreover, the transfer transaction had a value of zero ETH, thus making it impossible to confirm the reported sales amount ($11.8M).

Beeple’s CrossRoad, which was reportedly sold for $6.6M, was traded on Nifty, which uses an escrow contract (P3). Thus, it does not have any sale or transfer record on the blockchain (P1). Likewise, no public history exists for the sale of Beeple’s OceanFront (P1, P3). In fact, querying the blockchain with ownerOf (_tokenId) returns the address of the Nifty gateway as its current owner.

For both the WWW source code and Micaiah’s Replicator, the advertised payment amounts are not verifiable from the blockchain transfer records (P4). And Twitter CEO Jack Dorsey’s first tweet was sold on a platform called Valuables. This marketplace also uses an escrow contract, and, therefore, no sales or transfer details are publicly available (P1, P3). At the time of writing, querying the Valuables token contract on the Polygon sidechain returns an address owned by the platform as the owner.

C NON-TECHNICAL ASPECTS OF THE ECOSYSTEM

In this section, we discuss a few non-technical questions surrounding the NFT ecosystem. While we don’t claim to be legal experts nor do we offer any tax advise, we frequently encountered certain issues during our work and wanted to bring them to our readers’ attention.

Misconceptions around NFT purchase. Here we clarify some frequent misperceptions of the users interacting with the NFT space. (i) Originality. Since digital artworks are infinitely and identically reproducible, the “originality” of a piece of art in the NFT world is ascertained by the smart contract managing the corresponding token. Unfortunately, fraudsters have been able to trick victims into buying NFTs pointing to someone else’s art, for example, by deploying their own smart contracts. The NFT infrastructure is unable to provide any technical solution to this issue. (ii) Ownership. NFTs are used to introduce the concept of “ownership” to digital art. However, what that format of ownership actually means is somewhat subjective to individual’s interpretations. When an NFT is purchased, what the buyer really purchases is the NFT “token” on a blockchain. Whether and how that purchase translates to the ownership of the linked digital asset is debatable. (iii) Copyright. “Copyright” grants the owner of the copyright the rights to control (a) the manufacture of copies of the original piece, (b) the sale, licensing, or transferring of the copyright itself, and (c) who can produce “derivatives.” Merely purchasing an NFT does not transfer the copyright to the buyer. In one common scenario, the buyer posts the linked artwork to social media. This essentially creates a digital copy of the art. Therefore, this might infringe on the copyright of the artist, unless the terms of sale (ToS) explicitly allows the NFT buyer to do so. (iv) Terms of sale. A frequent misconception in the NFT space is that the ToS are encoded in the smart contract. Smart contracts are executable code. Therefore, they can enforce certain aspects related to a trade, such as the sales price and royalty. But what if the seller were to include a term that precludes buyers from using the underlying digital art for commercial purposes? A smart contract cannot enforce that provision. A seller would have to resort to traditional methods of enforcement, e.g., demand letters, litigation, etc.

Valuation of NFT collections. The value people place in a work of art is largely subjective. In the past, the price of an artwork has typically been decided by community consensus. Moreover, a (valuable) artwork typically has a rich history associated with it. The fact that the NFT market is so young means that such history is not available. As a result, a certain amount of hype (and maybe market manipulation) drives up prices. For example, the descriptions of a large number of NFT projects are rife with hyperbole, and it is not uncommon to find token owners on Twitter and Reddit providing long explanations of why a token they own is particularly meaningful. Since NFTs lack any intrinsic value, it is non-trivial for a newcomer to judge its true merit. Hence, they can easily fall prey of such promotions, and sometimes run into exit scams.

Tax implications. Law practitioners seem to agree that the purchase or sale of NFTs is a taxable transfer of property, and is therefore subject to capital gains tax. We noticed users gifting NFTs to others, which might trigger a gift tax. Unfortunately, taxation on NFTs is still a gray zone, as the tax laws are unclear and classic securities laws need to be reapplied. NFTMs are open markets, and cross-border sales
can make matters complicated, as NFT buyers and sellers have to deal with different jurisdictions’ tax regimes. Also, NFT trades could violate U.S. sanctions law, which prevents U.S. residents or citizens from conducting business with individuals or entities from sanctioned nations. Experts are not even ruling out the possibility of NFTs being used for money laundering to support illicit activities. While taxation regulations are already complicated, none of our examined marketplace places help user to remain tax-compliant by generating tax forms, e.g., 1099K. Instead, we see disclaimers such as OpenSea’s terms of service (ToS), which states: “You are solely responsible for determining what, if any, taxes apply to your Crypto Assets transactions. Neither OpenSea nor any other OpenSea Party is responsible for determining the taxes that apply to Crypto Assets transactions.” Given the lack of clarity and support, it is possible for unsuspecting, law-abiding users to inadvertently violate tax rules while interacting with these marketplaces.

Lack of support for selling physical assets. Though NFTs are being used to trade physical assets in limited cases, the current state of the affairs not only violates the basic principles of blockchain sales, but also it gives rise to the potential of abuse. NFTMs enable two mutually distrusting parties to execute trades in a trustless environment while retaining their anonymity. However, delivery of physical goods requires sharing the details of the buyer with the seller. In a centralized marketplace, e.g., Amazon, the platform itself acts as the trusted third-party (TTP) that protects the buyer information from the seller, often handling the delivery on the seller’s behalf. Unfortunately, no current NFTM offers such a service. In fact, even if they would do so, that would violate the spirit of a trustless, peer-to-peer marketplace. The alternative, which is the current practice, is to have the buyer share her contact details directly with the seller. For example, it is not uncommon to find NFTs sold by photograp- hers who promise the buyer a physical print of the photo, and, therefore, they request the buyer to email their address to the seller. Needless to say, this poses a significant threat to the buyer’s privacy. In addition, the absence of a TTP makes arbitration harder in case of any disputes, e.g., non-delivery of the purchased asset. To summarize, no current marketplace protocol satisfies all desirable yet mutually conflicting requirements, viz., trustlessness, decentralization, and anonymity. Thus, NFT markets are not entirely suitable as platforms to sell physical assets.

D CONTRACT ADDRESSES
We provide the Ethereum addresses of the important contracts used in this paper in Table 5. The following section describes the fraudulent user behaviors.

E FRAUDULENT USER BEHAVIORS - EXTENDED

Digital scarcity. Digital scarcity [14] is the limitation, typically imposed through software, to control the abundance of a digital resource. The more abundant an asset is, the lesser becomes its intrinsic value. Since NFTs are created by smart contracts, it is possible to impose appropriate limitations to ensure scarcity, provided: (i) the rarity parameter is stored on-chain, and (ii) the contract uses the parameter to prohibit minting beyond promised limits.

Currently, most of the items that claim to be a limited edition, or rare—it is word of mouth, by any contract-level guarantee. In fact, we found users complaining about a ‘supposed’ limited edition item being minted beyond the promised limit. Cryptomotors, a verified collection in OpenSea, claims to have only 150 GEN1 cars in circulation. However, the rarity parameter (GEN) is stored off-chain inside the JSON metadata, making it impossible to enforce rarity at the contract level. Additionally, the total Supply parameter, which controls the total supply of a token, is also not fixed, which makes it possible to mint unlimited cars.

Giveaway scams. NFT giveaways are campaigns to distribute free NFTs in exchange for having users promote the newly launched collection on social media. In giveaway scams, scammers lure the users with free NFTs, but ask for ‘small’ fees to cover the gas cost. In reality, they ask for fees greater than the gas cost required for the transaction. Sometimes, NFT platforms use a fungible token as the native currency for their services. For example, NFT-ART.FINANCE [31] is powered by their platform token called SNFTART. In some scams, the scammers pretend to put either the NFT, or the platform token ‘on-sale’. Users who fall for this fund sends to the designated accounts, but never receive the NFT or the tokens in return. Interestingly, there have also been instances where legitimate giveaways were targeted by scammers who impersonated the ‘winner’ by making social media accounts, and had the reward transferred to their wallet, thus forfeiting the real winner.

Front-running. In a front-running attack, an attacker gets a malicious transaction mined before a victim by paying a higher gas reward transferred to their wallet, thus forfeiting the real winner. In a front-running attack, a replay attack synthesizes a malicious transaction from a profit-making mempool transaction, oftentimes just by copying the arguments verbatim—only to front-run the victim to bag the profit. In reality, automated bots sniff the mempool for profitable victims. Since NFTs are managed by smart contracts, those are susceptible to front-running.

Also, it has been shown that by merely front-running the giveBirth call [22] of the CryptoKitties token, an attacker would make a profit.

Table 6: Details of the data collected for this study.
of $111K USD. In February 2021, an attacker exploited a weakness in CryptoPunks’s bid acceptance mechanism [13], for which a bid that was supposed to be closed for 26.25 ETH, returned only 1 Wei ($= 10^{-18}$ ETH) in profit due to being front-run.

**Insider trading.** An insider is one who has access to some confidential information about publicly traded security. Any trade involving an insider is an insider trade. However, it is illegal when the investor leverages that information in deciding when to buy or sell the security, because it gives them an unfair advantage to make a profit from that information. The regulatory gap in the NFT ecosystem surfaced out recently once again when an OpenSea employee was found to be involved in an illegal insider trade in September 2021. Leveraging internal information, that employee bought NFT just before it was featured on the front page of the marketplace, and then sold it right after it soared in price—making a profit of 18.875 ETH in total.

F **ARTIFACTS**

The data related to the NFTs and NFT marketplace activities that we collected over a period of time for the purpose of this study is one of our claimed contribution. Since the size of the data is in several terabytes, preparing it in a form usable by the reviewers, and then uploading it to an external service could take several hours to days. We have already promised to release the code and the dataset upon acceptance. Nevertheless, if the reviewers feel the need of having access to the dataset as part of the review process, we will make the requested subset available during the rebuttal phase.

G **DATA COLLECTION**

In Table 6, we provide the details of the types of data, i.e., assets and events we collected from different marketplaces and blockchain.
